Package 'clv'

September 28, 2023

Title Cluster Validation Techniques

Version 0.3-2.4

Author Lukasz Nieweglowski <wookashn@gmail.com>

Maintainer Lukasz Nieweglowski <wookashn@gmail.com>

Description Package contains most of the popular internal and external
cluster validation methods ready to use for the most of the
outputs produced by functions coming from package ``cluster''.
Package contains also functions and examples of usage for
cluster stability approach that might be applied to algorithms
implemented in ``cluster'' package as well as user defined
clustering algorithms.

cls.attrib   *Mean, cluster size and center - cluster utilities*

Description

Mean, center of each cluster, number of objects in each cluster - informations retrieved from partitioned data using `cls.attrib`.

Usage

```
cls.attrib(data, clust)
```

Arguments

data	numeric `matrix` or `data.frame` where columns correspond to variables and rows to observations.
clust	integer `vector` with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.

Value

As a result function returns object of `list` type which contains three objects with information about:
`mean` - numeric `vector` which represents mean of given data,
`cluster.center` - numeric `matrix` where columns correspond to variables and rows to observations,
`cluster.size` - integer `vector` with information about size of each cluster.

Author(s)

Lukasz Nieweglowski

See Also

Result of function is mostly used to compute following indicies: `clv.Dis`, `wcls.matrix`, `bcls.matrix`.

Examples

```
# create "data" matrix
mx <- matrix(0,4,2)
mx[2,1] = mx[3,2] = mx[4,1] = mx[4,2] = 1
# give information about cluster assignment
clust = as.integer(c(1,1,2,2))
cls.attrib(mx,clust)
```

`cls.scatt.data`	*Intercluster distances and intracluster diameters - Internal Measures*

Description

Two functions which find most popular *intercluster distances* and *intracluster diameters*.

Usage

```
cls.scatt.data(data, clust, dist="euclidean")
cls.scatt.diss.mx(diss.mx, clust)
```

Arguments

`data`	numeric `matrix` or `data.frame` where columns correspond to variables and rows to observations
`diss.mx`	square, symmetric numeric `matrix` or `data.frame`, representation of dissimilarity matrix where infomartion about distances between objects is stored.
`clust`	integer `vector` with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.
`dist`	chosen metric: "euclidean" (default value), "manhattan", "correlation" (variable enable only in `cls.scatt.data` function).

Details

Six *intercluster distances* and three *intracluster diameters* can be used to calculate such validity indices as *Dunn* and *Davies-Bouldin* like. Let $d(x,y)$ be a distance function between two objects comming from our data set.

Intracluster diameters

The *complete diameter* represents the distance between two the most remote objects belonging to the same cluster.

diam1(C) = max{ d(x,y): x,y belongs to cluster C }

The *average diameter* distance defines the average distance between all of the samples belonging to the same cluster.

diam2(C) = 1/|C|(|C|-1) * sum{ forall x,y belongs to cluster C and x != y } d(x,y)

The *centroid diameter* distance reflects the double average distance between all of the samples and the cluster's center (v(C) - cluster center).

diam3(C) = 1/|C| * sum{ forall x belonging to cluster C} d(x,v(C))

Intercluster distances

The *single linkage* distance defines the closest distance between two samples belonging to two different clusters.

dist1(Ci,Cj) = min{ d(x,y): x belongs to Ci and y to Cj cluster }

The *complete linkage* distance represents the distance between the most remote samples belonging to two different clusters.

dist2(Ci,Cj) = max{ d(x,y): x belongs to Ci and y to Cj cluster }

The *average linkage* distance defines the average distance between all of the samples belonging to two different clusters.

dist3(Ci,Cj) = 1/(|Ci|*|Cj|) * sum{ forall x belongs Ci and y to Cj } d(x,y)

The *centroid linkage* distance reflects the distance between the centres of two clusters (v(i), v(j) - clusters' centers).

dist4(Ci,Cj) = d(v(i), V(j))

The *average of centroids linkage* represents the distance between the centre of a cluster and all of samples belonging to a different cluster.

dist5(Ci,Cj) = 1/(|Ci|+|Cj|) * (sum{ forall x belongs Ci } d(x,v(j)) + sum{ forall y belongs Cj } d(y,v(i)))

Hausdorff metrics are based on the discovery of a maximal distance from samples of one cluster to the nearest sample of another cluster.

dist6(Ci,Cj) = max{ distH(Ci,Cj), distH(Cj,Ci) }

where: distH(A,B) = max{ min{ d(x,y): y belongs to B}: x belongs to A }

Value

`cls.scatt.data` returns an object of class `"list"`. Intracluster diameters: `intracls.complete`, `intracls.average`, `intracls.centroid`, are stored in vectors and intercluster distances: `intercls.single`, `intercls.complete`, `intercls.average`, `intercls.centroid`, `intercls.ave_to_cent`, `intercls.hausdorff` in symmetric matrices. Vectors' lengths and both dimensions of each matrix are equal to number of clusters. Additionally in result list `cluster.center` matrix (rows correspond to clusters centers) and `cluster.size` vector is given (information about size of each cluster).

`cls.scatt.diss.mx` returns an object of class `"list"`. Intracluster diameters: `intracls.complete`, `intracls.average`, are stored in vectors and intercluster distances: `intercls.single`, `intercls.complete`, `intercls.average`, `intercls.hausdorff` in symmetric matrices. Vectors' lengths and both dimensions of each matrix are equal to number of clusters. Additionally in result list `cluster.size` vector is given (information about size of each cluster).

Result used in: `clv.Dunn`, `clv.Davies.Bouldin`.

Examples

```
# load and prepare data
library(clv)
data(iris)
iris.data <- iris[,1:4]

# cluster data
pam.mod <- pam(iris.data,5) # create five clusters
v.pred <- as.integer(pam.mod$clustering) # get cluster ids associated to given data objects

# compute intercluster distances and intracluster diameters
cls.scatt1 <- cls.scatt.data(iris.data, v.pred)
cls.scatt2 <- cls.scatt.data(iris.data, v.pred, dist="manhattan")
cls.scatt3 <- cls.scatt.data(iris.data, v.pred, dist="correlation")

# the same using dissimilarity matrix
iris.diss.mx <- as.matrix(daisy(iris.data))
cls.scatt4 <- cls.scatt.diss.mx(iris.diss.mx, v.pred)
```

---

cls.set.section *Section of two subsets - External Measure utilities*

Description

Function finds section of two different subsets comming from the same data set.

Usage

```
cls.set.section(clust1, clust2)
```

Arguments

clust1   n x 2 integer `matrix` or `data.frame`. First column gives information about object number in data set in increasing order. Second column store information about cluster id the object is assigned to. If matrix is not an integer type, it will be coerced with warning.

clust2   n x 2 integer `matrix` or `data.frame`. First column gives information about object number in data set in increasing order. Second column store information about cluster id the object is assigned to. If matrix is not an integer type, it will be coerced with warning.

Details

Let A and B be two different subsamples of the same data set. Each subset is partitioned into P(A) and P(B) cluster sets. Information about object and cluster id's for pairs (A,P(A)) and (B,P(B)) are stored in `matrices clust1` and `clust2`. Function creates matrix which represents section of A and B.

Value

`cls.set.section` returns a n x 3 integer `matrix`. First column gives information about object number in dataset in increasing order. Second column store information about cluster id the object is assigned to. Information is taken from `clust1 vector` The same is for the third column but cluster id is taken from `vector clust2`.

Function preapres data for further computation. Result mostly is used in: `std.ext`, `dot.product`, `confusion.matrix`

Examples

```
# create two different subsamples
mx1 <- matrix(as.integer( c(1,2,3,4,5,6,1,1,2,2,3,3) ), 6, 2 )
mx2 <- matrix(as.integer( c(1,2,4,5,6,7,1,1,2,2,3,3) ), 6, 2 )
# find section
m = cls.set.section(mx1,mx2)
```

---

cls.stab.sim.ind   *Cluster Stability - Similarity Index and Pattern-wise Stability Approaches*

Description

`cls.stab.sim.ind` and `cls.stab.opt.assign` reports validation measures for clustering results. Both functions return lists of cluster stability results computed according to similarity index and pattern-wise stability approaches.

Usage

```
cls.stab.sim.ind( data, cl.num, rep.num, subset.ratio, clust.method,
                  method.type, sim.ind.type, fast, ... )
cls.stab.opt.assign( data, cl.num, rep.num, subset.ratio, clust.method,
                     method.type, fast, ... )
```

Arguments

data	numeric `matrix` or `data.frame` where columns correspond to variables and rows to observations.
cl.num	integer `vector` with information about numbers of cluster to which `data` will be partitioned. If vector is not an integer type, it will be coerced with warning.
rep.num	integer number which tells how many pairs of data subsets will be partitioned for particular number of clusters. The results of partitioning for given pair of subsets is used to compute similarity indices (in case of cls.stab.sim.ind) or *pattern-wise stability* (in case of cls.stab.opt.assign, for more details see references). By default rep.num value is 10. If wrong argument is applied it will be repaced with default value.
subset.ratio	a number comming from (0,1) section which tells how big data subsets should be. 0 means empty subset, 1 means all data. By default subset.ratio is set to 0.75. If wrong argument is applied it will be repaced with default value.
clust.method	string vector with names of cluster algorithms to be used. Available are: "agnes", "diana", "hclust", "kmeans", "pam", "clara". Combinations are also possible. By default c(″agnes″,″pam″) vector is applied.
method.type	string vector with information useful only in context of "agnes" and "hclust" algorithms . Available are: "single", "average", "complete", "ward" and "weighted" (for more details see [agnes](), [hclust]()). The last type is applicable only for "agnes". Combinations are also possible. By default c(″single″,″average″) vector is applied.
sim.ind.type	string vector with information useful only for cls.stab.sim.ind function. User is able to choose which similarity indices (external measures) to use to compare two partitionings. Available are: "dot.pr", "sim.ind", "rand", "jaccard" (for more details see [similarity.index](), [dot.product](), [std.ext]()). Combinations are also possible. By default c(″dot.pr″,″sim.ind″) vector is applied.
fast	logical argument which sets the way of computing cluster stability for hierarchical algorithms. By default it is set to TRUE, which means that each result produced by hierarchical algorithm is partitioned for the number of clusters chosen in cl.num argument and given clustering results are put for further computation. In this way computation of cluster stability is faster. If wrong argument is applied it will be repaced with default value.
...	additional parameters for clustering algorithms. Note: use with caution! Different clustering methods chosen in clust.method have different set of parameter names - mixing them often disallow any cluster algorithm to run.

Details

Both functions realize cluster stability approaches described in *Detecting stable clusters using principal component analysis* (see references).

The cls.stab.sim.ind function realizes algorithm given in *chapter 3.1* where only cosine similarity index (see [dot.product]()) is introduced as a similarity index between two different partitionings. This function realize this cluster stability approach also for other similarity indices such us [similarity.index](), [clv.Rand]() and [clv.Jaccard](). The important thing is that similarity index

(if chosen) produced by this function is not exactly the same as index produced by `similarity.index` function. The value of the `similarity.index` is a number which depends on number of clusters. Eg. if two "n-clusters" partitionings are compared the value always will be a number which belong to the `[1/n, 1]` section. That means the results produced by this similarity index are not comparable for different number of clusters. That's why each result is scaled thanks to the linear function `f:[1/n, 1] -> [0, 1]` where "n" is a number of clusters. The results' layout is described in *Value* section.

The `cls.stab.opt.assign` function realizes algorithm given in *chapter 3.2* where *pattern-wise agreement* and *pattern-wise stability* was introduced. Function returns the lowest *pattern-wise stability* value for given number of clusters. The results' layout is described in *Value* section.

It often happens that clustering algorithms can't produce amount of clusters that user wants. In this situation only the warning is produced and cluster stability is computed for partitionings with unequal number of clusters.

The cluster stability will not be calculated for all cluster numbers that are bigger than the subset size. For example if `data` contains about 20 objects and the `subset.ratio` equals 0.5 then the highest cluster number to calculate is 10. In that case all elements above 10 will be removed from `cl.num` vector.

Value

`cls.stab.sim.ind` returns a list of lists of matrices. Each matrix consists of the set of external similarity indices (which one similarity index see below) where number of columns is equal to `cl.num` vector length and row number is equal to `rep.num` value what means that each column contain a set of similarity indices computed for fixed number of clusters. The order of the matricides depends on three input arguments: `clust.method`, `method.type`, and `sim.ind.type`. Combination of `clust.method` and `method.type` give a names for elements listed in the first list. Each element of this list is also a list type where each element name correspond to one of similarity index type chosen thanks to `sim.ind.type` argument. The order of the names exactly match to the order given in those arguments description. It is easy to understand after considering the following example. Let say we are running `cls.stab.sim.ind` with default arguments then the results will be given in the following order: $agnes.single$dot.pr, $agnes.single$sim.ind, $agnes.average$dot.pr, $agnes.average$sim.ind, pamdot.pr, pamsim.ind.

`cls.stab.opt.assign` returns a list of vectors. Each vector consists of the set of cluster stability indices described in *Detecting stable clusters using principal component analysis* (see references). Vector length is equal to `cl.num` vector length what means that each position in vector is assigned to proper clusters' number given in `cl.num` argument. The order of the vectors depends on two input arguments: `clust.method`, `method.type`. The order of the names exactly match to the order given in arguments description. It is easy to understand after considering the following example. Let say we are running cls.stab.opt.assign with c("pam", "kmeans", "hclust", "agnes") as `clust.method` and c("ward","average") as `method.type` then the results will be given in the following order: $hclust.average, $hclust.ward, $agnes.average, $agnes.ward, $kmeans, $pam.

boxplot(res1$agnes.average$sim.ind)
plot(res2$hclust.single)
```

`cls.stab.sim.ind.usr`	*Cluster Stability - Similarity Index and Pattern-wise Stability Approaches with User Defined Cluster Algorithms*

Description

`cls.stab.sim.ind.usr` and `cls.stab.opt.assign.usr` reports validation measures for clustering results. Both functions return lists of cluster stability results computed for user defined cluster algorithms according to similarity index and pattern-wise stability approaches.

Usage

```
cls.stab.sim.ind.usr( data, cl.num, clust.alg, sim.ind.type, rep.num, subset.ratio )
cls.stab.opt.assign.usr( data, cl.num, clust.alg, rep.num, subset.ratio )
cls.alg( clust.method, clust.wrap, fast )
```

Arguments

data	numeric `matrix` or `data.frame` where columns correspond to variables and rows to observations.
cl.num	integer `vector` with information about numbers of cluster to which `data` will be partitioned. If vector is not an integer type, it will be coerced with warning.
clust.alg	there are two possible types of input:
	1. clustering function that takes two arguments: "data" to be partitioned described in `data` section and "clust.num" that represents number of cluster to which data will be partitioned. Function represents partitioning algorithm.
	2. an object of type "cls.alg" returned by `cls.alg` function (see "Details" for explanation). Object represents hierarchical algorithm.
clust.method	hierarchical clustering function that takes only one argument named "data" described in `data` section. Function should return hierarchical structure that might be applied as parameter to `clust.wrap` function.
clust.wrap	cluster function that takes exactly two arguments: "clust.res" that represents the result of `clust.method` function and "clust.num" which is the number of clusters to which "clust.res" is going to be cut. Function should return integer vector that represents object id (comming from `data` set) to cluster id (integer between 1 and `clust.num`) association.
sim.ind.type	string vector with information useful only for cls.stab.sim.ind.usr function. User is able to choose which similarity indicies (external measures) to use to compare two partitionings. Available are: "dot.pr", "sim.ind", "rand", "jaccard" (for more details see [similarity.index](#), [dot.product](#), [std.ext](#)). Combinations are also possible. By default c(*"dot.pr"*,*"sim.ind"*) vector is applied.
rep.num	integer number which tells how many pairs of data subsets will be partitioned for particular number of clusters. The results of partitioning for given pair of subsets is used to compute similarity indices (in case of cls.stab.sim.ind.usr) or *pattern-wise stability* (in case of cls.stab.opt.assign.usr, for more details see references). By default rep.num value is 10. If wrong argument is applied it will be repaced with default value.
subset.ratio	a number comming from (0,1) section which tells how big data subsets should be. 0 means empty subset, 1 means all data. By default subset.ratio is set to 0.75. If wrong argument is applied it will be repaced with default value.
fast	logical argument which sets the way of computing cluster stability for hierarchical algorithms. By default it is set to TRUE, which means that each result produced by hierarchical algorithm is partitioned for the number of clusters chosen in cl.num argument and given clustering results are put for further computation. In this way computation of cluster stability is faster. If wrong argument is applied it will be repaced with default value.

Details

Both functions realize cluster stability approaches described in *Detecting stable clusters using principal component analysis* chapters *3.1* and *3.2* (see references).

The `cls.stab.sim.ind.usr` as well as `cls.stab.opt.assign.usr` do the same thing as `cls.stab.sim.ind` and `cls.stab.opt.assign` functions. Main difference is that using this functions user is able to define and apply its own cluster algorithm to measure its cluster stability. For that reason `clust.alg` argument is introduced. This argument may represent partitioning algorithm (by passing it directly as a function) or hierarchical algorithm (by passing an object of "cls.alg" type produced by `cls.alg` function).

If a partitioning algorithm is going to be used the decalration of this function that represents this algorithm should always look like this: `function(data, clust.num) { ... return(integer.vector)}`. As an output function should always return integer vector that represents single clustering result on `data`.

If a hierarchical algorithm is going to be used user has to use helper `cls.alg` function that produces an object of "cls.alg" type. This object encapsulates a pair of methods that are used in hierarchical version (which is faster if the `fast` argument is not FALSE) of cluster stability approach. These methods are:
1. *clust.method* - which builds hierarchical structure that might be cut. The declaration of this function should always look like this one: `function(data) { ... return(hierarchical.struct) }` ,
2. *clust.wrap* - which cuts this hierarchical structure to `clust.num` clusters. This function definition should always look like this one: `function(clust.res, clust.num) { ... return(integer.vector)}`. As an output function should always return integer vector that represents single clustering result on `clust.res`.

`cls.alg` function has also third argument that indicates if fast computation should be taken (when TRUE) or if these two methods should be converted to one partitioning algorithm and to be run as a normal partitioning algorithm.

Well defined cluster functions "f" should always follow this rules (size(data) means number of object to be partitioned, res - integer vector with cluster ids):
1. when `data` is empty or `cl.num` is less than 2 or more than `size(data)` then `f(data, cl.num)` returns error. 2. if `f(data, cl.num)` -> res then length(res) == size(data),
3. if `f(data, cl.num)` -> res then for all "elem" in "res" the folowing condition is true: $0 <$ elem $<=$ `cl.num`.

It often happens that clustering algorithms can't produce amount of clusters that user wants. In this situation only the warning is produced and cluster stability is computed for partitionings with unequal number of clusters.

The cluster stability will not be calculated for all cluster numbers that are bigger than the subset size. For example if `data` contains about 20 objects and the `subset.ratio` equals 0.5 then the highest cluster number to calculate is 10. In that case all elements above 10 will be removed from `cl.num` vector.

Value

`cls.stab.sim.ind.usr` returns a lists of matrices. Each matrix consists of the set of external similarity indices (which one similarity index see below) where number of columns is equal to `cl.num` vector length and row number is equal to `rep.num` value what means that each column contain a

set of similarity indices computed for fixed number of clusters. The order of the matrices depends on `sim.ind.type` argument. Each element of this list correspond to one of similarity index type chosen thanks to `sim.ind.type` argument. The order of the names exactly match to the order given in those arguments description.

`cls.stab.opt.assign.usr` returns a vector. The vector consists of the set of cluster stability indices described in *Detecting stable clusters using principal component analysis* chapter *3.2* (see references). Vector length is equal to `cl.num` vector length what means that each position in vector is assigned to proper clusters' number given in `cl.num` argument.

---

clv.Davies.Bouldin   *Davies-Bouldin Index - Internal Measure*

Description

Function computes *Dunn index* - internal measure for given data and its partitioning.

Usage

```
clv.Davies.Bouldin( index.list, intracls, intercls)
```

Arguments

index.list   object returned by function `cls.scatt.data` or `cls.scatt.diss.mx`.

intracls   string vector containing one or more names of intra cluster distances. Available
                are:

     1. if index.list is produced by `cls.scatt.data`: complete | average | centroid,
     2. if index.list is produced by `cls.scatt.diss.mx`: complete | average.

intercls   string vector containing one or more names of inter cluster diameters. Avail-
                able are:

1. if index.list is produced by `cls.scatt.data`: single | complete | average | centroid | aveToCent | hausdorff.
2. if index.list is produced by `cls.scatt.diss.mx`: single | complete | average | hausdorff.

Details

Davies-Bouldin index is given by equation:

DB = (1/|C|) sum{forall i in 1:|C|} max[i != j] { (diam(Ci) + diam(Cj))/dist(Ci,Cj) }

       i,j   - numbers of clusters which come from the same partitioning,
      dist(Ck,Cl)   - inter cluster distance between clusters Ck and Cl,

diam(Cm)	- intra cluster diameter computed for cluster Cm,
|C|	- number of clusters.

Value

As output user gets the matrix of *Davies-Bouldin* indices. Matrix dimension depends on how many *diam* and *dist* measures are chosen by the user, normally dim(D)=c(length(intercls),length(intracls)). Each pair: (inter-cluster dist, intra-cluster diam) have its own position in result matrix.

  )
Davies.Bouldin <- function(data,clust)
  clv.Davies.Bouldin( cls.scatt.data(data,clust),
    intracls = c("complete","average","centroid"),
    intercls = c("single", "complete", "average","centroid", "aveToCent", "hausdorff")
  )

# compute indicies
dunn2 <- Dunn(iris.data, v.pred)
davies2 <- Davies.Bouldin(iris.data, v.pred)
```

---

clv.Dens_bw   *Inter-cluster density - Internal Measure*

Description

Function computes *inter-cluster density*.

Usage

```
clv.DensBw(data, clust, scatt.obj, dist="euclidean")
```

Arguments

data	matrix or data.frame where columns correspond to variables and rows to observations
clust	integer vector with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.
scatt.obj	object returned by clv.Scatt function.
dist	chosen metric: "euclidean" (default value), "manhattan", "correlation"

Details

The definition of *inter-cluster density* is given by equation:

Dens_bw = 1/(|C|*(|C|-1)) * sum{forall i in 1:|C|} sum{forall j in 1:|C| and j != i} *density*(u(i,j))/max{*density*(v(i)), *density*(v(j))}

where:

|C|	- number of clusters,
v(i), v(j)	- centers of clusters i and j,
u(i,j)	- middle point of the line segment defined by the clusters' centers v(i), v(j),
density(x)	- see below.

Let define function f(x,u):

$$f(x,u) = 0 \quad \text{if dist(x,u)} > stdev \text{ (} stdev \text{ is defined in } \texttt{clv.Scatt)}$$
$$f(x,u) = 1 \quad \text{otherwise}$$

Function *f* is used in definition of *density*(u):

density(u) = sum{forall i in 1:n(i,j)} f(xi,u)

where n(i,j) is the number of objects which belongs to clusters i and j and xi is such object.

This value is used by `clv.SDbw`.

Value

As result `Dens_bw` value is returned.

v.pred <- as.integer(cutree(agnes.mod,5)) # "cut" the tree

# compute Dens_bw index
scatt <- clv.Scatt(iris.data, v.pred)
dens.bw <- clv.DensBw(iris.data, v.pred, scatt)
```

---

clv.Dis   *Total separation between clusters - Internal Measure*

Description

Function computes *total separation between clusters*.

Usage

```
clv.Dis(cluster.center)
```

Arguments

cluster.center   numeric `matrix` or `data.frame` where columns correspond to variables and rows cluster centers.

Details

The definition of total separation between clusters is given by equation:

`Dis` = (Dmax/Dmin) * sum{forall i in 1:|C|} 1 /(sum{forall j in 1:|C|} ||vi - vj||)

where:

|C|	- number of clusters,
vi, vj	- centers of clusters i and j,
Dmax	- defined as: max{||vi - vj||: vi,vj - centers of clusters },
Dmin	- defined as: min{||vi - vj||: vi,vj - centers of clusters },
||x||	- means: sqrt(x*x').

This value is a part of `clv.SD` and `clv.SDbw`.

Value

As result `Dis` value is returned.

v.pred <- as.integer(cutree(agnes.mod,5)) # "cut" the tree

# compute Dis index
scatt <- clv.Scatt(iris.data, v.pred)
dis <- clv.Dis(scatt$cluster.center)
```

clv.Dunn   *Dunn Index - Internal Measure*

Description

Function computes *Dunn index* - internal measure for given data and its partitioning.

Usage

```
clv.Dunn( index.list, intracls, intercls)
```

Arguments

index.list   object returned by function `cls.scatt.data` or `cls.scatt.diss.mx`.

intracls   string `vector` containing one or more names of intra cluster distances. Available
                    are:

    1. if `index.list` is produced by `cls.scatt.data`: complete | average | centroid,
    2. if `index.list` is produced by `cls.scatt.diss.mx`: complete | average.

intercls   string `vector` containing one or more names of inter cluster diameters. Avail-
                    able are:

1. if `index.list` is produced by `cls.scatt.data`: single | complete | average | centroid | aveToCent | hausdorff.
2. if `index.list` is produced by `cls.scatt.diss.mx`: single | complete | average | hausdorff.

Details

Dunn index:

D = [min{ k,l - numbers of clusters } *dist*(Ck, Cl)]/[max{ m - cluster number } *diam*(Cm)]

k,l,m	- numbers of clusters which come from the same partitioning,
dist(Ck,Cl)	- inter cluster distance between clusters Ck and Cl,
diam(Cm)	- intra cluster diameter computed for cluster Cm.

Value

As output user gets matrix of *Dunn* indices. Matrix dimension depends on how many *diam* and *dist*
measures are chosen by the user, normally dim(D)=c(length(intercls),length(intracls)).
Each pair: (inter-cluster dist, intra-cluster diam) have its own position in result matrix.

clv.Scatt	*Average scattering for clusters - Internal Measure*

Description

Function computes *average scattering for clusters*.

Usage

```
clv.Scatt(data, clust, dist="euclidean")
```

Arguments

data	numeric `matrix` or `data.frame` where columns correspond to variables and rows to observations
clust	integer `vector` with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.
dist	choosen metric: "euclidean" (default value), "manhattan", "correlation"

Details

Let *scatter for set* X assigned as *sigma*(X) be defined as vector of variances computed for particular dimensions. *Average scattering for clusters* is defined as:

Scatt = (1/|C|) * sum{forall i in 1:|C|} ||*sigma*(Ci)||/||*sigma*(X)||

where:

$$
\begin{array}{ll}
|C| & \text{- number of clusters,} \\
i & \text{- cluster id,} \\
Ci & \text{- cluster with id 'i',} \\
X & \text{- set with all objects,} \\
||x|| & \text{- sqrt(x*x').}
\end{array}
$$

Standard deviation is defined as:

stdev = (1/|C|) * sqrt(sum{forall i in 1:|C|} ||*sigma*(Ci)||)

Value

As result `list` with three values is returned.

Scatt	- *average scattering for clusters* value,
stdev	- *standard deviation* value,
cluster.center	- numeric `matrix` where columns correspond to variables and rows to cluster centers.

```

---

clv.SD, clv.SDbw   *SD, SDbw - Internal Measures*

Description

Function computes *SD* and *S_Dbw validity indices*.

Usage

```
clv.SD(scatt, dis, alfa)
clv.SDbw(scatt, dens)
```

Arguments

scatt	*average scattering for cluster* value computed using clv.Scatt function.
dis	*total separation between clusters* value computed using [clv.Dis](clv.Dis) function.
dens	*inter-cluster density* value computed using clv.DensBw function.
alfa	weighting factor (normally equal to Dis(cmax) where cmax is the maximum number of input clusters).

Details

SD validity index is defined by equation:

SD = *scatt**alfa + *dis*

where *scatt* means *average scattering for clusters* defined in `clv.Scatt`. *S_Dbw validity index* is defined by equation:

S_Dbw = *scatt* + *dens*

where *dens* is defined in `clv.DensBw`.

Value

As result of `clv.SD` function *SD validity index* is returned. As result of `clv.SDbw` function *S_Dbw validity index* is returned.

```

---

confusion.matrix *Confusion Matrix - External Measures, Cluster Stability*

Description

For two different partitioning function computes *confusion matrix*.

Usage

```
confusion.matrix(clust1, clust2)
```

Arguments

clust1   integer vector with information about cluster id the object is assigned to. If
          vector is not integer type, it will be coerced with warning.

clust2   integer vector with information about cluster id the object is assigned to. If
          vector is not integer type, it will be coerced with warning.

Details

Let P and P' be two different partitioning of the same data. Partitionings are represent as two vectors
clust1, clust2. Both vectors should have the same length. Confusion matrix measures the size
of intersection between clusters comming from P and P' according to equation:

M[i,j] = | intersection of P(i) and P'(j) |

where:

$$P(i) \quad \text{- cluster which belongs to partitioning P,}$$
$$P'(j) \quad \text{- cluster which belongs to partitioning P',}$$
$$|A| \quad \text{- cardinality of set A.}$$

Value

cls.set.section returns a n x m integer matrix where n = |P| and m = |P'| defined above.

Author(s)

Lukasz Nieweglowski

Result used in `similarity.index`.

Examples

```
# create two different subsamples
mx1 <- matrix(as.integer( c(1,2,3,4,5,6,1,1,2,2,3,3) ), 6, 2 )
mx2 <- matrix(as.integer( c(1,2,4,5,6,7,1,1,2,2,3,3) ), 6, 2 )
```

```
# find section
m = cls.set.section(mx1,mx2)
confusion.matrix(as.integer(m[,2]),as.integer(m[,3]))
```

---

connectivity   *Connectivity Index - Internal Measure*

Description

Function evaluates *connectivity* index.

Usage

```
connectivity(data,clust,neighbour.num, dist="euclidean")
connectivity.diss.mx(diss.mx,clust,neighbour.num)
```

Arguments

data	numeric matrix or data.frame where columns correspond to variables and rows to observations
diss.mx	square, symetric numeric matrix or data.frame, representation of dissimilarity matrix where infomartion about distances between objects is stored.
clust	integer vector with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.
neighbour.num	value which tells how many nearest neighbors for every object should be checked.
dist	chosen metric: "euclidean" (default value), "manhattan", "correlation" (variable enable only in connectivity function).

Details

For given data and its partitioning *connectivity* index is computed. For choosen pattern neighbour.num nearest neighbours are found and sorted from closest to most further. Alghorithm checks if those neighbours are assigned to the same cluster. At the beggining *connectivity* value is equal 0 and increase with value:

1/i	when i-th nearest neighbour is not assigned to the same cluster,
0	otherwise.

Procedure is repeated for all patterns which comming from our data set. All values received for particular pattern are added and creates main *connectivity* index.

Value

connectivity returns a *connectivity* value.

conn4 <- connectivity.diss.mx(iris.diss.mx, v.pred, 10)
```

---

dot.product   *Cosine similarity measure - External Measure, Cluster Stability*

Description

Similarity index based on dot product is the measure which estimates how those two different partitionings, that comming from one dataset, are different from each other.

Usage

```
dot.product(clust1, clust2)
```

Arguments

clust1	integer vector with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.
clust2	integer vector with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.

Details

Two input `vectors` keep information about two different partitionings of the same subset comming from one data set. For each partitioning (let say P and P') its matrix representation is created. Let P[i,j] and P'[i,j] each defines as:

P[i,j] = 1 when object i and j belongs to the same cluster and i != j
P[i,j] = 0 in other case

Two matrices are needed to compute *dot product* using formula:

<P,P'> = sum(forall i and j) P[i,j]*P'[i,j]

This *dot product* satisfy Cauchy-Schwartz inequality <P,P'> <= <P,P>*<P',P'>. As result we get *cosine similarity measure*: <P,P'>/sqrt(<P,P>*<P',P'>)

Value

`dot.product` returns a *cosine similarity measure* of two partitionings. NaN is returned when in any partitioning each cluster contains only one object.

similarity.index   *Similarity index based on confusion matrix - External Measure, Cluster Stability*

Description

Similarity index based on confusion matrix is the measure which estimates how those two different partitionings, that comming from one dataset, are different from each other. For given matrix returned by [confusion.matrix](#) function *similarity index* is found.

Usage

```
similarity.index(cnf.mx)
```

Arguments

cnf.mx   not negative, integer matrix or data.frame which represents object returned
                by [confusion.matrix](#) function.

Details

Let M is n x m (n <= m) *confusion matrix* for partitionings P and P'. Any one to one function *sigma*: {1,2,...,n} -> {1,2,... ,m}. is called *assignment* (or also *association*). Using set of *assignment* functions, A(P,P') index defined as:

A(P,P') = max{ sum(forall i in 1:length(*sigma*)) M[i,*sigma(i)*]: *sigma* is an *assignment* }

is found. (*Assignment* which satisfy above equation is called *optimal assignment*). Using this value we can compute *similarity index* S(P.P') = (A(P,P') - 1)/(N - 1) where N is quantity of partitioned objects (here is equal to sum(M)).

Value

similarity.index returns value from section [0,1] which is a measure of similarity between two different partitionings. Value 1 means that we have two the same partitionings.

std.ext   *Standard External Measures: Rand index, Jaccard coefficient etc.*

Description

Group of functions which compute standard external measures such as: Rand statistic and Folkes and Mallows index, Jaccard coefficient etc.

Usage

```
std.ext(clust1, clust2)
clv.Rand(external.ind)
clv.Jaccard(external.ind)
clv.Folkes.Mallows(external.ind)
clv.Phi(external.ind)
clv.Russel.Rao(external.ind)
```

Arguments

clust1   integer vector with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.

clust2   integer `vector` with information about cluster id the object is assigned to. If
                vector is not integer type, it will be coerced with warning.

external.ind   `vector` or `list` with four values SS,SD,DS,DD which are result of function
                `std.ext`

Details

Two input `vectors` keep information about two different partitionings (let say P and P') of the same
data set X. We refer to a pair of points (xi, xj) (we assume that i != j) from the data set using the
following terms:

SS   - number of pairs where both points belongs to the same cluster in both partitionings,
SD   - number of pairs where both points belongs to the same cluster in partitioning P but in P' do not,
DS   - number of pairs where in partitioning P both point belongs to different clusters but in P' do not,
DD   - number of pairs where both objects belongs to different clusters in both partitionings.

Those values are used to compute (M = SS + SD + DS +DD):

Rand statistic	R = (SS + DD)/M
Jaccard coefficient	J = SS/(SS + SD + DS)
Folkes and Mallows index	FM = sqrt(SS/(SS + SD))*sqrt(SS/(SS + DS))
Russel and Rao index	RR = SS/M
Phi index	Ph = (SS*DD - SD*DS)/((SS+SD)(SS+DS)(SD+DD)(DS+DD)).

Value

`std.ext` returns a `list` containing four values: SS, SD, DS, DD.
`clv.Rand` returns R value.
`clv.Jaccard` returns J value.
`clv.Folkes.Mallows` returns FM value.
`clv.Phi` returns Ph value.
`clv.Russel.Rao` returns RR value.

Examples

```
# load and prepare data
library(clv)
data(iris)
iris.data <- iris[,1:4]

# cluster data
pam.mod <- pam(iris.data,3) # create three clusters
v.pred <- as.integer(pam.mod$clustering) # get cluster ids associated to given data objects
v.real <- as.integer(iris$Species) # get also real cluster ids

# compare true clustering with those given by the algorithm
# 1. optimal solution:

# use only once std.ext function
std <- std.ext(v.pred, v.real)
# to compute three indicies based on std.ext result
rand1 <- clv.Rand(std)
jaccard1 <- clv.Jaccard(std)
folk.mal1 <- clv.Folkes.Mallows(std)

# 2. functional solution:

# prepare set of functions which compare two clusterizations
Rand <- function(clust1,clust2) clv.Rand(std.ext(clust1,clust2))
Jaccard <- function(clust1,clust2) clv.Jaccard(std.ext(clust1,clust2))
Folkes.Mallows <- function(clust1,clust2) clv.Folkes.Mallows(std.ext(clust1,clust2))

# compute indicies
rand2 <- Rand(v.pred,v.real)
jaccard2 <- Jaccard(v.pred,v.real)
folk.mal2 <- Folkes.Mallows(v.pred,v.real)
```

wcls/bcls.matrix   *Matrix Cluster Scatter Measures*

Description

Functions compute two base matrix cluster scatter measures.

Usage

```
wcls.matrix(data,clust,cluster.center)
bcls.matrix(cluster.center,cluster.size,mean)
```

Arguments

data   numeric matrix or data.frame where columns correspond to variables and
                rows to observations

clust	integer vector with information about cluster id the object is assigned to. If vector is not integer type, it will be coerced with warning.
cluster.center	matrix or data.frame where columns correspond to variables and rows to cluster centers defined by data and clust parameters.
cluster.size	integer vector with information about size of each cluster computed using clust vector.
mean	*mean* of all data objects.

Details

There are two base matrix scatter measures.

1. *within-cluster scatter measure* defined as:

W = sum(forall k in 1:cluster.num) W(k)

where W(k) = sum(forall x) (x - m(k))*(x - m(k))'

$$
\begin{array}{ll}
x & \text{- object belongs to cluster k,} \\
m(k) & \text{- center of cluster k.}
\end{array}
$$

2. *between-cluster scatter measure* defined as:

B = sum(forall k in 1:cluster.num) |C(k)|*(m(k) - m)*(m(k) - m)'

$$
\begin{array}{ll}
|C(k)| & \text{- size of cluster k,} \\
m(k) & \text{- center of cluster k,} \\
m & \text{- center of all data objects.}
\end{array}
$$

Value

$$
\begin{array}{ll}
\text{wcls.matrix} & \text{returns W matrix (\textit{within-cluster scatter measure}),} \\
\text{bcls.matrix} & \text{returns B matrix (\textit{between-cluster scatter measure}).}
\end{array}
$$
